The role of mechanical stress in bone biology: effects of uniaxial cyclic strain on gene expression in osteoblast-like MC3T3-E1 cells. In bone, mechanical stress is a key regulator of both bone formation and remodeling. Mechanical force application to cells, although under certain circumstances it may also increase oxidative stress, has minimal, if any, deleterious effects on bone formation or remodeling processes. We hypothesized that an acute application of mechanical stress stimulates osteoblast differentiation and function and affects expression of specific genes potentially involved in bone cell signaling. We therefore tested the effect of a 1-hr application of a uniaxial cyclic strain of a magnitude that was expected to be sufficient to direct cells to adopt a differentiation phenotype. A rat-tail type II collagen fiber-ceramic cylinder was implanted and strain applied to the ceramics to induce a mechanical stress gradient from the periphery to the center of the implant over a 3-wk period. MC3T3-E1 cells were seeded onto the devices and cultured under unstrained conditions for up to 5 d. While unstrained cells did not show significant alterations in alkaline phosphatase (AP) or osteocalcin (OC) activities, cells subjected to mechanical strain produced a significant increase in both activities compared
